## Abstract

The global financial crisis has led to a renewed interest in discretionary fiscal stimulus. Advocates of discretionary measures emphasize that government spending can stimulate additional private spending — the Keynesian multiplier effect. Thus, we investigate whether the spending package announced by Euro area governments for 2009 and 2010 is likely to boost GDP by more than one for one. Because of modeling uncertainty, it is essential that such policy evaluations be robust to alternative modeling assumptions and parameterizations. We use five different empirical macroeconomic models with Keynesian features such as price and wage rigidities to evaluate the impact of the fiscal stimulus. Four of them suggest that the planned increase in government spending will reduce private consumption and investment significantly. Only a model that largely ignores the forward-looking behavioral response of consumers and firms implies crowding-in of private spending. We review a range of issues that may play a role in the recession of 2008-2009. Implementation lags are found to reinforce crowding-out and may even cause an initial contraction. Zero-bound effects may lead the central bank to abstain from interest rate hikes and increase the GDP impact of government spending. Crowding-in, however, requires an immediate anticipation of at least two years at the zero bound. Using a multi-country model, we find that spillovers between euro area countries are negligible or even negative, because direct demand effects are offset by the indirect effect of an euro appreciation. New-Keynesian DSGE models provide a strong case for government savings packages. Announced with sufficient lead time, spending cuts induce a significant short-run stimulus and crowding-in of private spending.

## Non-technical Summary

The global financial crisis has led to a renewed interest in discretionary fiscal stimulus. Proponents of fiscal stimulus emphasize the Keynesian multiplier effect. It follows from the national accounts' spending identity when combined with the text-book Keynesian consumption function. A country's gross domestic product is equated with total spending, which consists of private consumption, investment, net exports and government expenditures. Consumption is believed to increase with after-tax income. Consequently, a debt-financed increase in government spending boosts total spending (and therefore total GDP) more than one for one. Thus, we investigate whether the spending package announced by Euro area governments for 2009 and 2010 is likely to have such a multiplicative effect on euro area GDP. Because of modeling uncertainty, it is essential that such policy evaluations be robust to alternative modeling assumptions and parameterizations.

For this reason, we compare the impact of the fiscal packages using several empirically-estimated macroeconomic models of the euro area. The main focus is on model simulations of the planned increase in government spending rather than increases in transfers and tax rebates, because spending is supposed to exhibit the largest Keynesian multiplier effect. The models considered in this comparison are due to Smets and Wouters (2003), Laxton and Pesenti (2003), Ratto, Roeger, and in't Veld (2009), Taylor (1993) and Fagan, Henry, and Mestre (2005). They exhibit Keynesian features such as price and wage rigidities and were estimated to fit euro area data. All but the model of Fagan et al. (2005) incorporate forward-looking decision-making by households and firms and are best characterized as New Keynesian models. The first three models incorporate extensive microeconomic foundations and are typically referred to as DSGE (dynamic stochastic general equilibrium) models. All the models are made available in a new macroeconomic model archive for comparative analysis described in more detail in Wieland, Cwik, Mueller, Schmidt, and Wolters (2009).

In the baseline scenario, New-Keynesian models provide no support for a traditional Keynesian multiplier effect. The European spending plans would result in a reduction in private sector spending for consumption and investment purposes. Households and firms reduce spending in anticipation of future tax burdens and higher interest rates. By contrast, the model of Fagan et al. (2005) largely ignores forward-looking motives for private decision-making and provides a more traditional Keynesian perspective. This model supports a strong Keynesian multiplier effect, but the boom is followed by a bust. Thus, the cumulative effect of government on private spending eventually turns negative. More importantly, models with backward-looking dynamics are not as well-suited for the analysis of major policy changes as the New-Keynesian models. Instead, they are used primarily for short-term forecasting.

We then discuss a number of factors that may have played a role in the recession of 2008 and 2009. Time lags arise because of the steps needed to move from a timely announcement to actual

implementation of government spending plans. Such implementation lags lead to more crowding out and may even cause an initial contraction. In a deep recession, the zero-bound on nominal interest rates may cause the central bank to abstain to raise interest rates in response to a fiscal stimulus as in normal times, because its notional interest target is below zero. Such implicit monetary accommodation increases the GDP impact of government spending. Crowding-in, however, requires an immediate anticipation of at least two years at the zero bound.

In addition, we use the multi-country model of Taylor (1993) to assess the likely spill-over effects within the euro area. Since half of the euro area stimulus is derived from the German stimulus plan, we investigate the spill-over effect of German spending in the absence of similar measures in other euro area countries. We find that the positive direct demand effect of German spending on other euro area economies is largely offset by the indirect negative effect of an euro appreciation.

We also investigate the implications of government investment and transfers in one of the above-mentioned models. Finally, we review the recent data on government spending and the recovery from recession, and turn to the question of fiscal consolidation. We illustrate that New-Keynesian DSGE models provide a strong-case for government savings packages. Announced with sufficient lead time, anticipated future spending cuts induce a significant short-run stimulus and sustained crowding-in of private spending.

# 1 Introduction

In 2008 and early 2009 governments around the world announced major fiscal stimulus packages. Resorting to discretionary fiscal policy to an unprecedented degree, they hoped to alleviate the recessionary impact of the global financial crisis. U.S. Congress, for example, approved 787 billion dollars of additional spending, transfers and tax reductions with the 2009 *American Recovery and Reinvestment Act*. The European Union initiated the *European Economic Recovery Plan* while national European governments announced their own fiscal stimuli. The German government, which was initially criticized for not spending enough, eventually announced two "Konjunkturpakete" in a row.<sup>1</sup>

The impact of such announcements and the implied measures is difficult to assess, because many factors play a role. Proponents of fiscal stimulus emphasize the Keynesian multiplier effect. It follows from the national accounts' spending identity when combined with the text-book Keynesian consumption function. A country's gross domestic product is equated with total spending, which consists of private consumption, investment, net exports and government expenditures. Consumption is believed to increase with after-tax income. Consequently, a debt-financed increase in government spending boosts total spending (and therefore total GDP) more than one for one.<sup>2</sup> Since spending may partly be diverted to imports, proponents have lobbied for coordinated stimulus packages across Europe. Critics of fiscal stimulus, however, argue that government spending will displace private consumption and investment (cf. Barro (2009)). Consumers will anticipate future tax burdens and save rather than spend, while government borrowing will drive up interest rates and crowd out private investment.

In a recent paper Christina Romer, Chair of the U.S. President's Council of Economic Advisers, and Jared Bernstein, Chief Economist of the Office of the Vice-President, provided numerical estimates of the impact of an increase in government spending on GDP and employment in the United States. They estimate that an increase in government purchases of 1 percent of GDP would induce an increase in real GDP of 1.6 percent compared to what it otherwise would be.<sup>3</sup> Given this multiplier

---

<sup>1</sup>A prominent critic was Paul Krugman, who accused the German government of "boneheadedness" in an article in the New York Times of Dec 12, 2008, titled "The economic consequences of Mr. Steinbrück". He wrote: "*The world economy is in a terrifying nose-dive, yet Mr. Steinbrueck, (the German finance minister) is standing firm against any extraordinary fiscal measures, ... In Europe it is very hard to do a fiscal expansion unless it is coordinated ... The reason is that the European economy is so integrated ... As a result, the multiplier on fiscal expansion within any given European country is much less than the multiplier on a coordinated fiscal expansion. ... if Germany prevents an effective European response, this adds significantly to the severity of the global downturn. ... in short, there's a huge multiplier effect at work; unfortunately, what it's doing is multiplying the impact of the current German government's boneheadedness.*"

<sup>2</sup>The national accounts spending identity is given by,  $Y = C + I + EX - IM + G$ . The Keynesian consumption function implies that consumption increases with after-tax income:  $0 < dC/d(Y - T) < 1$ . It is then concluded that a debt-financed increase in government spending boosts total spending by more than one for one:  $1 < dY/dG = 1/(1 - dC/d(Y - T))$ .

<sup>3</sup>See Romer and Bernstein (2009), Appendix 1, page 12. This paper was written during the transition period in early January before Christina Romer was sworn in as Chair of the Council of Economic Advisers.

effect they project that a package similar in size to the ARRA legislation would boost U.S. GDP by 3.6 percent. Cogan, Cwik, Taylor, and Wieland (2010), however, show that this conclusion is not robust.<sup>4</sup> Government spending multipliers in alternative, empirically estimated New-Keynesian models are much smaller. For example, estimates of the GDP effects of ARRA legislation obtained with the model of Smets and Wouters (2007) are only one-sixth as large as the estimates of Romer and Bernstein (2009).

This paper aims to assess the magnitude of the stimulus programs announced by Euro area governments in 2008 and 2009 and quantify their effect on economic activity. A macroeconomic model is needed to distinguish the impact of government actions on the economy from other factors. Because of modeling uncertainty, it is essential that policy evaluations be robust to alternative assumptions. For this reason, we compare the impact of the fiscal packages using several empirically-estimated macroeconomic models of the euro area. The main focus is on model simulations of the planned increase in government spending rather than increases in transfers and tax rebates, because spending is supposed to exhibit the largest Keynesian multiplier effect.

The models considered in this comparison are due to Smets and Wouters (2003), Laxton and Pesenti (2003), Ratto et al. (2009), Taylor (1993) and Fagan et al. (2005).<sup>5</sup> All five models exhibit Keynesian features such as sluggish adjustment due to price and wage rigidities. Thus, they are well-suited to investigate possible rationales for Keynesian demand management. Several of these models have been developed and used at policy institutions such as the European Central Bank, the European Commission, or the International Monetary Fund. The first four model are best described as New-Keynesian models. These models account for forward-looking decisions by households and firms that anticipate future changes in government policies. The models of Smets and Wouters (2003), Laxton and Pesenti (2003) and Ratto et al. (2009) also belong to the class of models often referred to as New-Keynesian dynamic stochastic general equilibrium (DSGE) models. Such models fully incorporate recent advances in terms of microeconomic foundations from real-business-cycle models and combine them with Keynesian-style rigidities.

In the baseline scenario, New-Keynesian models provide no support for a traditional Keynesian

---

<sup>4</sup>The working paper version of Cogan, Cwik, Taylor, and Wieland (2009) appeared shortly after the ARRA had passed the House and the Senate.

<sup>5</sup>The models are made available in a new macroeconomic model archive for comparative analysis described in more detail in Wieland et al. (2009). While macroeconomic model comparison projects have helped produce some very influential insights such as the Taylor rule, they have been infrequent and costly, because they require the input of many teams of researchers and multiple meetings to obtain a limited set of comparative findings (see, for example, Taylor (1999) and Hughes-Hallett and Wallis (2004)). The new comparative approach to model-based research and policy analysis presented in Wieland et al. (2009) instead enables individual researchers to conduct model comparisons easily, frequently, at low cost and on a large scale. Note, the models collected were not available "off-the-shelf". Rather the above-mentioned project involved a substantial work effort in order to create such a "shelf" with models that have been checked for replicability and augmented with a common variable, shock and policy rule space to allow proper comparative exercises. For analysis of monetary policy in the United States and the euro area see Taylor and Wieland (2009) and Kuester and Wieland (2010), respectively.

multiplier effect. The European spending plans would result in a reduction in private sector spending for consumption and investment purposes. Households and firms reduce spending in anticipation of future tax burdens and higher interest rates. By contrast, the model of Fagan et al. (2005) largely ignores forward-looking motives for private decision-making and provides a more traditional Keynesian perspective. This model supports a strong Keynesian multiplier effect, but the boom is followed by a bust. Thus, the cumulative effect of government on private spending eventually turns negative. More importantly, models with backward-looking dynamics are not as well-suited for the analysis of major policy changes as the New-Keynesian models. Instead, they are used primarily for short-term forecasting.

We then discuss a number of factors that may have played a role in the recession of 2008 and 2009. Time lags arise because of the steps needed to move from a timely announcement to actual implementation of government spending plans. Such implementation lags lead to more crowding out and may even cause an initial contraction. In a deep recession, the zero-bound on nominal interest rates may cause the central bank to abstain to raise interest rates in response to a fiscal stimulus as in normal times, because its notional interest target is below zero. Such implicit monetary accommodation increases the GDP impact of government spending. Crowding-in, however, requires an immediate anticipation of at least two years at the zero bound.

In addition, we use the multi-country model of Taylor (1993) to assess the likely spill-over effects within the euro area. Since half of the euro area stimulus is derived from the German stimulus plan, we investigate the spill-over effect of German spending in the absence of similar measures in other euro area countries. We find that the positive direct demand effect of German spending on other euro area economies is largely offset by the indirect negative effect of an euro appreciation.

We also investigate the implications of government investment and transfers in one of the above-mentioned models. Finally, we review the recent data on government spending and the recovery from recession, and turn to the question of fiscal consolidation. We illustrate that New-Keynesian DSGE models provide a strong-case for government savings packages. Announced with sufficient lead time, anticipated future spending cuts induce a significant short-run stimulus and sustained crowding-in of private spending.

## **2 Euro area fiscal stimulus packages for 2009 and 2010**

As the first step of this project, we investigated the magnitude of the different stimulus measures announced by national euro area governments under the auspices of the European Economic Recovery Plan. To this end, we reviewed the stability programs that national finance ministries publicly submitted to the ECOFIN Council in line with the Stability and Growth Pact in 2008 and 2009 (see, for example, French Ministry of Finance (2009) or Spanish Ministry of Finance (2009)). On this basis,

we obtained numerical estimates of the amounts to be allocated to additional government purchases, transfers and tax reductions for 2009 and 2010. In doing so we compared our estimates against those obtained by Saha and von Weizsäcker (2009) for spending, transfers and tax measures in 2009. Thus, our findings made available in the working paper version in July 2009 comprised the first set of such estimates that covered both years of the stimulus plan.<sup>6</sup>

The total sum of measures we were able to identify for the eleven largest economies of the euro area comes to 95.5 bln Euro in 2009 and 78.6 bln Euro in 2010. This is 1.04 percent of euro area GDP in 2009 and 0.86 per cent in 2010. Indeed, the euro area stimulus package is much smaller than the ARRA legislation in the United States that amounted to roughly 5 percent of GDP.<sup>7</sup> However, the European package is concentrated on two years and front-loaded in 2009, while the U.S. stimulus is spread over five years building up towards a peak in 2010 and declining slowly over 2011 and 2012 (see Cogan et al (2010)). In this manner, the European authorities appeared to adhere more to the idea of "temporary" stimulus, favored by institutions such as the International Monetary Fund, rather than the sustained stimulus advocated by advisers of the U.S. administration.

**Table 1** provides an overview of our findings of discretionary measures by country. In terms of GDP, these 11 economies account for 99 percent of the euro area.

<sup>6</sup>See Cwik and Wieland (2009), CEPR Discussion Paper No. 7389.

<sup>7</sup>The working paper version of Cogan et al (2010) (NBER Working Paper, No. 14782, March 2009) offered a first estimate of quarterly spending, transfers and tax measures from the ARRA shortly after it became law. Romer and Bernstein (2009) used different numbers from the Administration's plan before it passed Congress.

More detailed information on the specific measures in each country and a breakdown in terms of government spending, transfers, tax cuts and other measures is provided in **Appendix A**. Since we focus on studying the effect of discretionary measures, changes in fiscal balances resulting from automatic stabilizers are not included. **Table 1** reports information on the total amount of the respective fiscal package and the implied increase in government spending separately. The total also includes temporary tax cuts and transfers. The amounts are reported in billions of Euro and in relative shares in percent of 2008 GDP.

The fiscal stimuli differ substantially in terms of magnitude and composition. By far the largest stimulus package has been enacted in Germany: 88.8 bln Euro spread over 2009 and 2010. In relative terms these measures amount to 3.55 percent of GDP. Thus, the German package is approaching the magnitude of the ARRA stimulus in the United States adjusted for the size of the economy. However, the U.S. measures are spread over four years. The German stimulus corresponds to 51 percent of the total EU-11 stimulus according to the information we have been able to put together. In terms of government expenditures, the German share in the EU-11 stimulus comes to 46 percent.

The second largest package was announced by the Spanish government, roughly 41.5 billion Euro, and the third largest is the French stimulus of about 21 billion Euro. Measures in some smaller countries such as Austria and Finland are also significant relative to GDP. Other countries launched smaller fiscal measures. Some countries that were in a particularly weak fiscal position such as Greece or Ireland initiated no significant stimulus. Also, Italy apparently initiated very little additional spending and increased some taxes and tax collection.

The fiscal stimulus packages vary in terms of the measures undertaken. Finland and the Netherlands adopted measures mainly on the revenue side whereas Portugal and France increased government spending. In the euro area as a whole roughly 36 percent of the fiscal stimulus packages are increases in direct government spending. Roughly 9 percent are transfers and 55 percent are attributed to tax cuts.

The largest multiplier effect is to be expected from government purchases. Direct purchases and similar spending as part of the euro area stimulus come to 0.48 percent of 2008 GDP in 2009 and 0.20 percent in 2010. Among such purchases, those with an investment character offer the possibility of a longer-term improvement in the productive capacity of the euro area economy. Of course, there may exist a tendency by national authorities to describe as many government spending initiatives as possible as a form of investment. Thus we try to separate out spending measures that are clearly aimed at creating new infrastructure that may help develop private business. Such infrastructure government spending amounts to 0.19 and 0.13 percent of GDP in 2009 and 2010 respectively. Country-specific breakdowns are reported in the appendix.

### 3 Estimating the GDP impact of announced government spending

A macroeconomic model is needed to evaluate the impact of government policy measures on economic activity in isolation from other disturbances that may currently influence actual economic outcomes. Structural models make it possible to identify the role of market expectations, the effect of announcements of plans for future policy decisions, and the impact of fiscal measures under alternative assumptions of likely monetary policy responses. In their analysis of the U.S. stimulus, Cogan et al. (2010) considered two empirically estimated macroeconomic models of the U.S. economy, one developed by Taylor (1993) and the other one by Smets and Wouters (2007). The Smets and Wouters model, in particular, is representative of current thinking in macroeconomics. It is very similar to, and "largely based on" according to Smets and Wouters, another well-known empirically-estimated New-Keynesian DSGE model developed by Christiano, Eichenbaum, and Evans (2005). In a related paper that came out of a new modeling effort at the European Central Bank, Smets and Wouters (2003) estimated such a model for the euro area.

The euro area is still a young monetary union. Historical relationships may have changed due to the shift in monetary regime and comparable cross-country data series are limited and short. The euro area model of Smets and Wouters (2003), for example, is estimated with historical, pre-EMU data. Their euro area measures are artificial aggregates obtained by adding up national data from a period of differential monetary policies and fixed but adjustable exchange rates. As shown by Kuester and Wieland (2010) modeling uncertainty is particularly pronounced in the euro area and comparative analysis is crucial to obtain robust policy conclusions. To this end we make use of the new database of macroeconomic models designed explicitly with the purpose of doing such policy evaluations and robustness studies (see Wieland et al. (2009) and Taylor and Wieland (2009)).

Text-book Keynesian analysis suggests that direct government purchases have a greater multiplier effect than tax reductions or additional transfers. Thus, we start by comparing the estimated impact of the additional spending announced by national governments (7th and 8th column in Table 1) on euro area GDP in three medium-scale New-Keynesian DSGE models: the Smets-Wouters (SW) model developed at the European Central Bank, the model of Laxton and Pesenti (2003) developed at the International Monetary Fund, and the model of European Commission researchers Ratto et al. (2009).

The Laxton and Pesenti (2003) model was created about at the same time as the SW model. It includes two countries, the euro area and the Czech republic. Its parameters were not estimated with macroeconomic data but calibrated to values considered reasonable by the modelers in light of other studies and euro area and Czech macroeconomic volatility. In our model comparison it is labeled the "Small IMF model" because IMF researchers have also developed several larger macroeconomic models of the world economy.<sup>8</sup> The open-economy model of the euro area by Ratto et al. (2009)

---

<sup>8</sup>One such model is MULTIMOD, a dynamic multi-country macro model of the world economy (see Laxton, Isard,

is estimated with quarterly euro area data from 1981Q1 to 2006Q1 thereby including a large part of EMU history. They named their model "QUEST III" and we refer to it as the "EU-Quest" model.

All three models assume forward-looking (rational) expectations by individuals and firms, monopolistic competition and nominal rigidities in goods and labor markets. Price and wage rigidities are motivated with Calvo-style staggered contracts (SW model) or adjustment costs (Small IMF and EU-Quest models). The models fully incorporate microeconomic foundations consistent with the optimizing decision-making of representative households and firms, similar to earlier real-business cycle models that assumed fully flexible prices. The models have in common that they include a number of additional constraints or frictions that help in matching the dynamics and persistence of some key macroeconomic time series. These frictions include price and wage indexation, habit-persistence in consumption, investment adjustment costs, serially correlated shocks and costs related to variable capital utilization (SW and EU-Quest models).

With regard to the analysis of fiscal stimulus it is important to highlight the following differences between the three models. The Laxton and Pesenti (2003) model is the only one which allows for the possibility that additional demand is diverted towards cheaper imports in place of domestic goods, though perhaps to limited extent because the foreign country from the perspective of the euro area is rather small. The EU-Quest model provides a more thorough treatment of the government sector than the other two models. It includes policy rules for government spending, transfers and consumption, capital and income tax rates and uses data on these variables in estimation. Another important departure from the assumptions made by Smets and Wouters (2003) and Laxton and Pesenti (2003) concerns the treatment of households. These models have been criticized for assuming that all households are forward-looking and optimize their spending decisions. Instead, it has been proposed that one allows for the possibility that many households follow "rules of thumb" like the original Keynesian consumption function with a constant marginal propensity to consume, or that they are constrained to consume all their current income (see, for example, Gali, López-Salido, and Vallés (2007)). Ratto et al. (2009) estimate that 35 % of households in the euro area are liquidity-constrained in this manner.<sup>9</sup>

**Figure 1** reports the increase in government expenditures (bar chart) together with the resulting effect on euro area real GDP in each of the three models. It is assumed that governments are able to start spending immediately in the first quarter of 2009. The initial increase is phased in below the

---

Faruqee, Prasad, and Turtelboom (1998) for an introduction). Its companion model with microeconomic foundations is called Global Economy Model (GEM) and described in Pesenti (2008). More recently, IMF researchers developed another structural model for the analysis of fiscal and monetary policy called GIMF that is described in Kumhof and Laxton (2007) and used in recent contributions to the policy debate. Unfortunately, the parameters of the GIMF model are also calibrated and not estimated.

<sup>9</sup>This finding is similar to euro area estimates of 25 to 35% by Coenen and Straub (2005) and 30 to 40% by Forni, Monteforte, and Sessa (2009). For the United States Cogan et al. (2010) obtained an estimate of 27% rule-of-thumb households.

average of 0.48 percent of GDP for 2009 and increases above the average level in the second part of the year.

Figure 1: Estimated GDP impact of government spending stimulus

New-Keynesian DSGE models of ECB, IMF and EU researchers

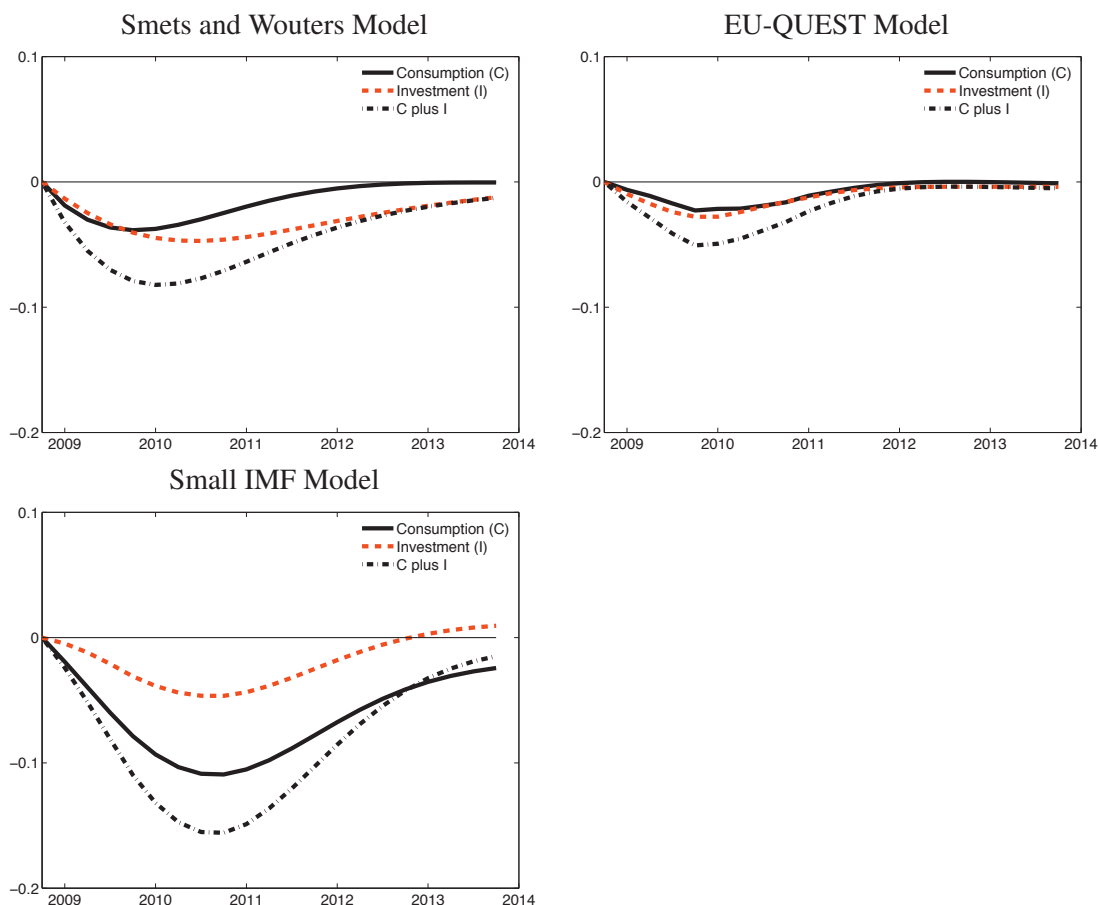

Notes: Quarterly annualized government spending is depicted by the bars in percent of GDP: 0.24 in 2009Q1, 0.48 in 2009Q2, 0.60 in 2009Q3 and 2009Q4 and 0.20 in 2010.

Euro area GDP increases as a result of additional government spending. However, the model simulations do not exhibit the text-book multiplier effect that would imply a greater than one-for-one increase in GDP relative to government spending. Instead, the increase in GDP is significantly smaller than the associated boost to government expenditures. Once government spending returns to baseline at the end of 2010, GDP even falls below baseline in the SW and Small IMF model. By implication, the increase in government spending must be displacing rather than multiplying private spending. As shown in **Figure 2**, the dynamic response of private sector demand for consumption or investment purposes is negative in all three models. Private consumption and investment decline immediately and stay below baseline until well after the end of the fiscal stimulus. The simulation assumes that consumers' and firms' expectations incorporate the time profile of government spending as announced by national governments.

These findings on European stimulus are similar to the results for the U.S. economy reported by Cogan et al. (2009). The mechanism of private sector displacement is related to the forward-looking perspective of households and firms. Households and firms anticipate from the start that government expenditures increase for two years in a row. They also anticipate that debt-financed expenditures will ultimately lead to higher taxes in the future. The negative wealth effect on private consumption of higher anticipated future taxes reduces the positive impact of the stimulus. In the SW and Small IMF

models, the increase in future taxes falls entirely on lump-sum non-distortionary taxes. In the EU-Quest model the response of consumption, capital and labor income tax rates is modeled with reaction functions but lump-sum taxes are also introduced to guarantee convergence of the debt-income ratio. To the extent lump-sum taxes play an important role in stabilizing debt dynamics after fiscal stimulus, these models understate the longer-term negative effect on growth coming from higher distortionary taxes (see Uhlig (2009)).

Figure 2: Consumption and investment responses to government spending stimulus

Notes: Consumption and investment deviations from steady-state are in percent of GDP.

All three models also exhibit a decline in investment following the government spending stimulus. Investment demand is influenced by the price of capital, expectations and adjustment costs. The mechanics of crowding-out of investment may be understood as follows. The government increases demand for final goods and firms respond by increasing production and employing more labor and capital. Wages and the rental rate of capital rise to bring about greater labor supply and capital utilization in equilibrium. Along with marginal cost inflation also rises. Monetary policy responds to higher output and inflation by raising nominal interest rates enough to achieve higher ex-ante real

interest rates. Expected higher real-interest rates depress the price of capital and discourage new investment. Though future increases in the rental rate of capital tend to boost the price of capital, the interest rate effect is found to dominate in the model simulations reported in **Figure 2**.

The crowding-out effect in 2010 and 2011 is largest in the Small IMF model, perhaps because it is a two-country model in which households have the option to buy more foreign goods if the price of domestic goods is pushed up by government demand. The EU-Quest model with 35 % rule-of-thumb households also exhibits crowding-out of consumption and investment. Output in EU-Quest increases initially even a bit less than in the other two models, but is slightly higher in 2010 and 2011. This finding may appear surprising, because it has been suggested that the presence of liquidity-constrained households can induce crowding-in of consumption following a government spending shock in New-Keynesian DSGE models (see for example Gali, Lopez-Salido, Valles (2007)). Indeed, if one takes a given model and increases the share of rule-of-thumb households while keeping all other parameters constant, the GDP effect of government stimulus increases, and with a large enough share consumption is crowded-in and a text-book Keynesian multiplier effect is realized. However, Coenen and Straub (2005) have shown that the empirically estimated share of constrained households is not sufficient to overturn the negative wealth effects that are internalized by the forward-looking households. This finding is confirmed by the EU-Quest model. Furthermore, Cogan et al. (2009) also estimate a model with rule-of-thumb households and find that the GDP impact of the ARRA government spending only increases by a small amount relative to a simulation with the model of Smets and Wouters (2007).

#### *Other Keynesian-style models*

Some have criticized New-Keynesian DSGE models for being too similar to real business cycle models and incorporating too little of the lessons derived from earlier New Keynesian models with rational expectations or more traditional Keynesian models with backward-looking dynamics. Thus, we introduce two more models in the comparison, the model of the G7 economies by Taylor (1993) and the ECB's area-wide model of Fagan et al. (2005).<sup>10</sup>

The Taylor model is interesting because it is a multi-country model. It allows us to look at euro area member economies such as France, Germany and Italy, separately. It is also best characterized as a New-Keynesian model because it combines forward-looking, rational expectations with nominal rigidities due to overlapping wage contracts. The model equations exhibit many similarities to those in the above-mentioned current-generation New-Keynesian DSGE models, but they are not derived as stringently from the optimization problems of representative households and firms. Consumption de-

<sup>10</sup>We use the linearized version of Dieppe, Kuester, and McAdam (2005).

mand is with the exception of Germany and Italy disaggregated into durable, nondurable and services consumption. Demand for these components is then modeled as a function of lagged consumption, current income, and expectations of future income and real interest rates over the next two years. The sensitivity of consumption demand to current income has an equivalent effect to the presence of rule-of-thumb consumers in the EU-Quest model. Fixed investment demand is also modeled as a function of lagged values, current and expected future demand and real interest rates over the next two years. The Taylor model assumes that monetary policy is set independently from seigniorage and government finance considerations and successfully controls inflation in the long-run. Thus, implicitly it is assumed that the long-run government budget constraint is satisfied, but tax and debt dynamics are not modeled explicitly as in the EU-Quest model. Output is assumed to return to its long-run potential that is treated as exogenous to monetary policy and government spending.

We simulate a euro area-wide fiscal stimulus for Germany, France and Italy combined. The exchange rates between these three economies are fixed. Short-term nominal interest rates are identical and set according to a policy rule with area-wide targets.<sup>11</sup> As shown in **Figure 3** the initial boost to GDP in the first three quarters of 2009 is slightly greater than in the SW, Small IMF and EU-Quest models. The effect on GDP is smaller than in the SW and EU-Quest models, however, in 2010 and slightly more negative in 2011. The left panel in **Figure 4** depicts the response of consumption and investment. A small crowding-in effect is observed in the first two quarters, but it is quickly overwhelmed and followed by a decline in consumption and investment. Some of the euro area stimulus is dissipated to increased demand for imports from outside the euro area.

Figure 3: The Taylor (1993) G-7 model and the ECB's area-wide model

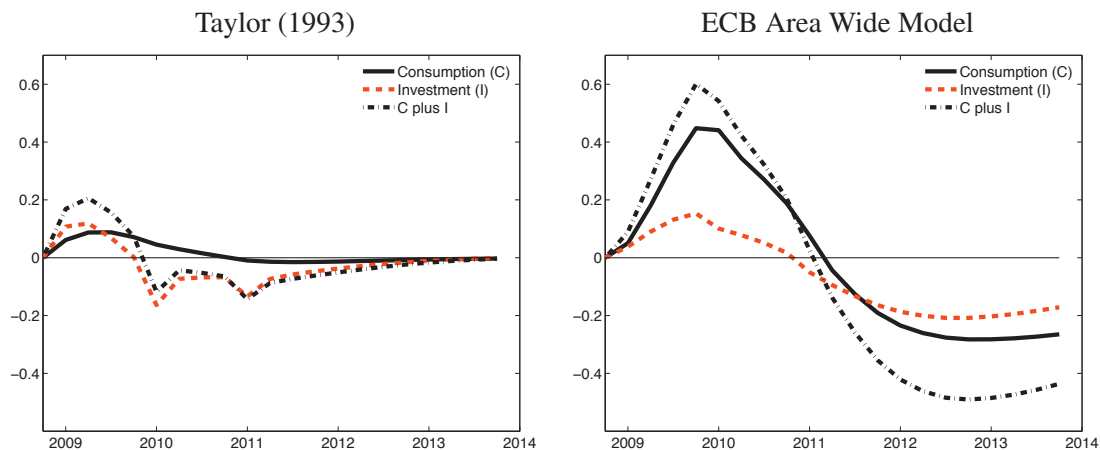

<sup>11</sup> Wieland (1996) previously used the Taylor model to study the implications of a shift from the Bundesbank-dominated European Monetary System with policy focused on German targets to a monetary union with area-wide targets.

The ECB's area-wide model provides a more traditional Keynesian outlook on fiscal stimulus. It exhibits significant crowding-in effects of consumption and investment (right panel in **Figure 4**) that raise output in 2010 twice as high as the remaining increase in government spending. This result is obtained, because the model assumes backward-looking behavior. Expectations are represented by lagged values of the variables to be forecasted. Furthermore, private consumption is modeled as a function of disposable income and wealth, with the latter defined as cumulative savings. Thus, households are not modeled as forward-looking decision makers. The simulation of the ECB's area-wide model indicates that the Keynesian multiplier effect in the first two and a half years will be followed by a significant slump in subsequent years. Such an oscillatory response is common to dynamic models with backward-looking dynamics. For example, a simple dynamic model of output with two lags can exhibit a hump-shaped response with subsequent overshooting with a coefficient above unity on the first lag and a large enough negative coefficient on the second lag. A possible source of such behavior are accelerator effects in investment. It is neglected by the text-book analysis of the Keynesian multiplier discussed in the introduction of this paper.

Figure 4: Consumption and investment responses in Taylor and ECB Area-Wide Model

Notes: Consumption and investment deviations from steady-state are in percent of GDP.

We conclude from this comparison that significant short-run Keynesian multiplier effects appear in models with backward-looking dynamics but disappear if forward-looking, optimizing motivations for households' and firms' decision making are allowed for in the analysis. It is noteworthy that models such as the ECB area-wide model have been criticized for assuming backward-looking, adaptive behavior. Fagan et al. (2005) themselves consider the backward-looking approach as adequate for short-term forecasts, but unsatisfactory with regard to the evaluation of major policy changes. Henry, de Cos, and Momigliano (2004) show that the introduction of more forward-looking

elements in the ECB area-wide model substantially reduce the government spending multiplier.<sup>12</sup> Recently, ECB staff have introduced a New-Area-Wide model, which is more similar to the Smets and Wouters and EU-Quest models (see Christoffel, Coenen, and Warne (2008)).

#### **4 Issues regarding fiscal stimulus in the current recession and financial crisis**

Recently, certain critics have demanded that policy makers completely disregard any analysis with current-generation macroeconomic models, because these models have failed to predict the global financial crisis and the ensuing recession of 2008 and 2009. Truth is, that these models did not only fail to predict this recession, but would also have failed to predict most if not all previous recessions. Wieland and Wolters (forthcoming), for example, investigate the forecasting performance of such models in the five most recent NBER-dated U.S. recessions based on the historically available data vintages. None of the models succeeds in predicting one of these recessions. However, this negative finding also applies to earlier generation macroeconomic models and structural VAR models. The models considered tend to attribute the onset of recessions to unexpected negative macroeconomic shocks. Interestingly, Wieland and Wolters (forthcoming) find that expert forecasts available from the Federal Reserve Staff and the consensus forecast from the Survey of Professional Forecasters also fail to predict recessions. They perform better than the macroeconomic models in estimating current quarter output by using higher frequency information available prior to the release of quarterly GDP data, but such "nowcasts" can similarly be used as initial conditions for model-based forecasts. Wieland and Wolters (forthcoming) find that mean model forecasts compare particularly well to professional forecasts at a horizon of three to four quarters and during recoveries, including the current recovery phase. Thus, we believe such models should not be so easily dismissed as tools for analyzing policy measures such as fiscal stimulus that form part of such economic recoveries from recession.

A related criticism points to the lack of a fully developed banking sector in these models. These critics argue therefore that such models do not help in understanding the aggregate consequences of the risks faced by banks in the current crisis. Indeed, that is true and the particular models we consider in this comparison have nothing to say on the effect of government actions such as credit guarantees or re-capitalization measures for struggling banks. Thus, this paper remains silent on these policy initiatives, except for noting that if they achieve their aim, they will support the predictability of the speed of return to more normal growth conditions by means of such models. The government

---

<sup>12</sup>Interestingly, the comparison of euro area macroeconomic models in Kuester and Wieland (2010) suggests that models which allow for an important influence of forward-looking decision-making by households and firms have fared better in terms of fitting euro area inflation and output dynamics since the start of monetary union.

spending stimulus we aim to assess, however, works directly via purchases of goods and services and generates additional demand that firm's satisfy by increasing labor input and capital utilization. This channel of transmission is very well captured in the models we consider in our analysis. Moreover, for those models that predict crowding-out of private investment due to the increase in government debt, potential difficulties in obtaining bank-based credit for new private sector investments would be less of a concern. A risk of greater-than-expected crowding-out, however, would have to be acknowledged.

Another concern regarding the relevance of the findings in the preceding section is that these simulations are initiated from the steady-state of the model rather than a deep recession state that would be more appropriate to the situation at the beginning of 2009. A first point in response is that for linear models, or the linearized versions of nonlinear models that we consider, there is no difference between an impulse response simulation initiated at the steady-state and one initiated at any other state. The marginal response of endogenous variables is independent of the state. To give an example, the marginal increase in the nominal interest rate in response to a given increase in output and inflation due to fiscal stimulus is the same, whether it occurs below, at, or above the neutral steady-state level of the nominal interest rate.

Of course, such a linear approach may not be considered fully satisfactory. Fortunately, however, we employ nonlinear solution techniques for rational expectations models in our simulations.<sup>13</sup> The nonlinear approach makes it possible to account for the anticipation of the announced time profile of the fiscal stimulus. Thus, our simulations do not treat each quarter increase to spending as a separate unexpected shock, nor are expectations computed based on the assumption of a simple auto-correlated process as in typical linear fiscal impulse simulations. Instead, households and firms anticipate the announced plan as of the first quarter of 2009. With the help of the nonlinear solution approach we will also address other nonlinearities that appear particularly relevant to this recession.

In the following we investigate three issues in further detail, the possibility of fiscal implementation lags, the possibility of an increase in so-called rule-of-thumb or liquidity-constrained households and the implications of the zero bound on nominal interest rates.

### *Implementation lags and negative stimulus*

A great advantage of the automatic fiscal stabilizers such as unemployment insurance or the tax system is that they apply immediately to cushion the consequences of a recession on households and firms and possibly even before the decline in economic activity has become widely apparent. If discretionary fiscal stimulus is intended to offset recessions then timeliness is of the essence but may be difficult to achieve. For example, the current recession in the euro area started in January 2008,

<sup>13</sup>The particular methodology we use is described in Juillard (1996) and implemented in DYNARE. This solution approach builds on earlier work by Laffarge (1990) and Fair and Taylor (1983).

according to the CEPR Business Cycle Dating Committee's judgement published in March 2009. The EERP and national stimulus were only announced by the end of 2008 or the beginning of 2009, once the onset of recession had become apparent. Given the difficulties of business and government experts in predicting recessions, this is not surprising.

More importantly, even if governments may be able to rush through legislation and make a rapid announcement, the actual implementation of the stimulus will still take more time. While some increases in transfers, such as the U.S. tax rebates in 2008 and 2009, may be delivered effectively within a few months of the announcement, it is more difficult to execute major new spending effectively in a short time. Certainly, getting started with the building of new infrastructure such as roads, bridges or canals, the improvement of facilities for delivery of government services, the repair of educational institutions and the hiring of new professional staff requires at least several months if it is done in an effective manner. Once government authorities have decided and planned specific budgets, the particular work projects still need to be selected. The offers of companies applying for tenders need to be prepared and then compared by the authorities. Furthermore, if such spending is pushed through too quickly chances for wastage increase because projects and labor are contracted without soliciting sufficiently competitive offers. In an attempt to recognize such practical limitations in the execution of the 2009 euro area stimulus, we shift the government spending plan in our simulations simply back by two quarters. Thus, the bulk of additional spending occurs from the third quarter of 2009 onwards with the profile of additional purchases otherwise unchanged. The resulting impact on GDP in the five models considered is shown in **Figure 5**.

Figure 5: Implementation lags and anticipation effects

The three-New Keynesian DSGE models (Smets and Wouters, Small IMF, EU-Quest) project that GDP will decline in the first half of 2009 due to the implementation lag. Thus, negative stimulus would occur just at the time when positive stimulus is most needed. This finding is particularly

disconcerting for proponents of fiscal stimulus, because this class of models is judged by many to be the best currently available framework for policy evaluation.<sup>14</sup> By contrast, the traditional backward-looking features of the ECB's area-wide model ensure that output remains unchanged in the first two quarters of 2009. In this model, the stimulative effects are realized once government spending is implemented successfully from summer 2009 onwards. Interestingly, the model of Taylor (1993) indicates the possibility of a slight boost ahead of the delayed stimulus.

Further insight regarding these differential results may be obtained from the comparison of consumption and investment responses. In the Smets and Wouters model and the Small IMF model the negative impact of the delayed government spending and the negative wealth effect on private consumption of higher anticipated future taxes combine to slow down the economy. Households and firms see through the future discretionary spending stimulus. They reduce spending immediately to save for higher taxes later. This effect also dominates in the EU-QUEST model even though one third of the households are constrained to consume current income. Similarly, the expectation of higher real interest rates down the line triggers a decline in investment demand following the announcement of fiscal stimulus, even if the actual government spending is only implemented by the third quarter of 2009.

The earlier-generation New-Keynesian model of Taylor (1993) does not generate the same strong Ricardian effects as the current vintage of New-Keynesian DSGE models. Households and firms in that make forward-looking decisions but only based on a two-year forecasting horizon. Thus, their expectations are influenced more by the positive impact of additional government spending in the near term. This expectation leads to additional spending in the first two quarters. Finally, the ECB's area-wide model essentially delivers the same assessment as in the simulation without implementation lag, except that the crowding-in of consumption and investment is delayed by two quarters. Again, backward-looking dynamics induce a big oscillatory effect. The boost is followed by a slump.

#### *The share of rule-of-thumb households in the recession*

So far we have treated the parameters of the models as constant throughout the analysis. One may well argue that some of those parameters may change in such a deep recession as observed in 2008 and 2009. In particular, the share of rule-of-thumb or liquidity-constrained households could change over time. This share is hard-wired into models such as EU-QUEST and implicit in the response to current income in models such as Taylor (1993) and the ECB's Area-Wide Model. Theoretically, one motivation for including such behavior in general equilibrium models is to approximate the share of

<sup>14</sup>See for example the survey of Woodford (2008).

households that would like to consume more and become borrowers in the current period. However, they are not able to obtain credit from banks on future expected income. Thus, they tend to consume any additional increase in current income.

A possible concern is that the share of similarly constrained households' has increased in the course of the financial crisis because banks were more reluctant to extend credit. Increasing the share of constrained households in the DSGE models considered previously while keeping all other parameters constant would reduce the crowding-out effect on consumption. As a result, the GDP effect of government spending would increase. At some point, with shares near or above 50 % a model such as the one developed by Smets and Wouters would imply that government spending increases output by more than one for one, because consumption rises too. The greater the share of rule-of-thumb consumers the more consumption demand in these models behaves as in the text-book Keynesian consumption function and induces the respective multiplier effect.

By contrast, it is also possible that the share of consumers that want to borrow declined during this deep recession. In particular, households who expect a longer-term reduction in life-time income, because of less promising job opportunities, asset losses, sustained unemployment, or higher taxes may decide to save more. In this manner some of those households that were borrowing-constrained before, may now want to save rather than spend any additional income they might receive due to government stimulus in form of a temporary increase in work hours in response to government purchases or in form of direct transfers.

The share of rule-of-thumb consumers in the three New-Keynesian DSGE models that we have considered ranges from 0% to 35%. Rather than running a range of simulations with other values we review recent empirical evidence on household behavior during this recession. In the United States, there have been two policy initiatives that offer useful natural experiments to shed light on the question of the share of households that consume any temporary increases in disposable income. These are the tax rebates in spring 2008 and spring 2009 issued by the Bush and Obama Administration. An aggregate comparison of disposable personal income and consumption is provided in Taylor (2009) and Taylor (2010a). The rebate payments are directly apparent as upward spikes in personal income in May-June 2008 and 2009 respectively. Aggregate consumption in those periods grows slowly and smoothly. It shows no immediate increase that would be a mirror image of these one-time transfers as it should be the case for rule-of-thumb consumers. Thus, the aggregate data does not indicate a straightforward inconsistency with the forward-looking consumption-smoothing behavior of optimizing households faced with temporary windfall income. A recent survey by Claudia Sahm and Slemrod (2010) sheds additional light on this issue. They find that 25 percent of households reported that the one-time economic stimulus payment in 2008 led them mostly to increase their spending. In 2009, it was 13 percent of households that report to have mostly spent the extra pay from the lower

withholding.

Another U.S. policy initiative, the "Cash for Clunkers" program in 2009, may also generate insights in optimizing versus rule-of-thumb behavior of households. Mian and Sufi (2010) claim evidence that almost all of the additional purchases under the program were pulled forward from the very near future, and that the effect was almost completely reversed by March 2010. Again this may be interpreted as evidence of large forward-looking optimizing consumption behavior.

Turning to Europe, some interesting survey evidence has been collected by Boersch-Supan, Bucher-Koenen, Gasche, and Ziegelmeier (2010). They survey households in Germany and obtain the following findings. About a third of the households respond that they have received additional income from the "Konjunkturpaket II" and have spent about 75% of this additional income on consumption. Asked whether they would spend a possible "consumption voucher" on goods that they would have bought anyway, or whether they would use it to increase their consumption, 73% of households answered that they would not increase overall consumption in case of receipt of such a voucher. Finally, this survey also included a question aimed to elicit the extent of Ricardian behavior in terms of the expectation of increased taxation following a rise a government spending. Interestingly, 75% of surveyed German households answered that they expect tax increases in the near future, and an additional 15% expected such tax increases somewhat later in the future.

We conclude from this recent empirical evidence regarding the consumption behavior of U.S. and German households during the financial crisis, that the range of assumptions regarding the share of rule-of-thumb consumers in the models used in our analysis already brackets the likely extent of such behavior during the crisis and recession. Thus, we do not further modify our simulation results in this regard.

#### *Monetary policy and the zero bound on nominal interest rates*

While fiscal policy is subject to political approval and suffers from implementation lags if additional spending is to be used effectively, the central bank can react immediately to the onset of recession by lowering nominal interest rates. Thus, monetary policy has a natural advantage over fiscal policy as a tool for recession fighting. However, monetary policy also faces certain constraints regarding the use of its most popular instrument. Currency provides savers with a non-interest bearing nominal store of value. The resulting zero-lower-bound on nominal interest rates puts a limit on the extent of interest rate easing. The implications of this constraint for monetary policy were analyzed almost 14 years ago by Fuhrer and Madigan (1997), Krugman (1998) and Orphanides and Wieland (1998). Orphanides and Wieland (1998)<sup>15</sup> evaluated the impact of this constraint on output and infla-

<sup>15</sup>A revised version was published as Coenen, Orphanides, and Wieland (2004).

tion variability in an estimated macroeconomic model of the U.S. economy with rational expectations and nominal rigidity similar to the Taylor (1993) model. They showed that large recessions would be deepened and disinflationary or deflationary effects strengthened when the zero-lower-bound is binding. However, the central bank does not turn powerless. Orphanides and Wieland (2000) find that optimal monetary policy involves preemptive interest reductions followed by quantitative easing. Direct asset purchases allow the reduction of risk and term premia and exploit real-balance and portfolio-balance effects in order to stimulate inflation and lower real interest rates. McCallum (2002), Svensson (2001) and Coenen and Wieland (2003) emphasized exchange rate policy as an additional tool when the space for interest rate easing is exhausted. Reifschneider and Williams (2000) showed how an announcement extending the period over which nominal interest rates are kept at zero in the future reduces the recessionary and deflationary consequences of the zero bound.

The zero-bound becomes a binding constraint when the central bank's notional interest target implied by a reaction function that describes its desired response to macroeconomic conditions turns negative. Cogan et al. (2010) have investigated to what extent this was the case in the U.S. economy in 2009. They simulated the Smets-Wouters (2007) model with the actual U.S. data through the first quarter of 2009. Then, they computed projections of the recovery implied by this model using a version that incorporated the non-negativity restriction on the federal funds rate. Whether or not the federal funds rate endogenously visits the zero bound is found to depend on the monetary policy rule that captures the Federal Reserve's response to economic developments. Under the well-known Taylor rule the simulated recovery is sufficiently quick so that Taylor's rule would prescribe an interest rate tightening away from zero. Under the estimated policy rule in the Smets-Wouters model the endogenous visit at the zero bounds lasts two quarters.

The euro area model simulations presented so far have been conducted under the assumption that ECB monetary policy follows an interest rate rule that stabilizes output and inflation. The particular policy rule that we have implemented in all the models considered in this paper is taken from Gerdesmeier and Roffia (2004). Including the same monetary policy rules in each model guarantees that diverging effects of fiscal stimulus are due to the economic structure rather than different monetary policy assumptions. The rule is estimated with euro area data. It was also used by Kuester and Wieland (2010) in a comparative study of the first generation of euro area models developed at the ECB. It is a rule for setting the short-time nominal interest rate,  $r_t$  as a function of inflation, output and the lagged interest rate:

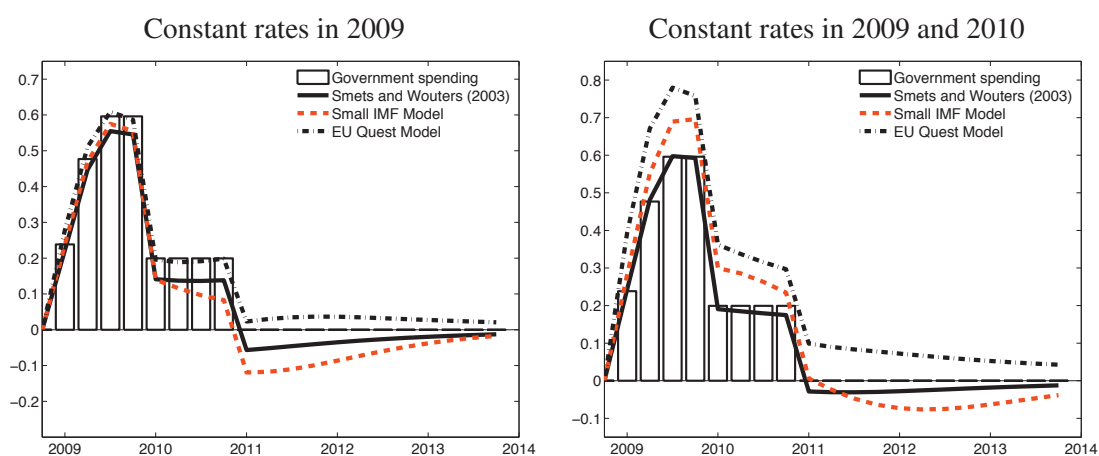

$$r_t = 0.66r_{t-1} + 0.66\pi_t + 0.10y_t \quad (1)$$

Here,  $r_t$  is the quarterly nominal interest rate (annualized),  $\pi_t$  is the year-on-year inflation rate and  $y_t$  is the output gap. Monthly data from 1985 to 2002 was used in estimation.

Next, we consider the possibility that the euro area recession is deep enough to ensure that the zero

bound is binding for one year. This assumption introduces an important nonlinearity in the model simulation. Because the notional interest rate target of the central bank is below zero, the nominal interest rate does not increase in response to fiscal stimulus. Instead, the nominal interest rate remains constant. As a result, the real interest rate falls somewhat during the first few quarters. The zero-lower-bound implicitly causes monetary accommodation of the increase in government spending. The simulation is identical to a scenario in which the ECB is assumed to promise keeping the nominal interest rate constant throughout 2009. In 2010 policy is assumed to return to the policy rule, thereby keeping inflation under control in the longer run.

Figure 6: GDP impact of stimulus when nominal interest remains constant

The effect of euro area government spending on GDP with constant interest rates in 2009 is shown in the left panel of **Figure 6**. Only the outcome for the three New-Keynesian DSGE models is shown and there is no implementation lag. Compared to the simulations in **Figure 1** GDP increases a bit more in response to the spending stimulus. The decline in real interest rates in the first few quarters holds up investment and consumption and reduces the crowding-out effect. Even so, crowding-out still dominates for the SW and Small IMF model. In the EU-Quest model, output roughly moves one-for-one with government spending.

The right panel in **Figure 6** displays simulations in which households and firms anticipate that the zero bound remains binding for two years. Thus, the nominal interest rate is anticipated to remain constant and does not rise in response to the fiscal stimulus until the first quarter of 2011. The expectation of rising inflation and falling real interest rates boosts consumption and investment and induces a noticeable crowding-in effect of consumption and investment in 2009 and 2010 in the EU-Quest and Small IMF models. In the SW model output roughly mirrors the movement in GDP. It is important to point out that this boost relies on the anticipation of two years of constant rates as of the first quarter of 2009. For example, if private sector participants anticipate interest rates to rise at

the end of 2009 and only realize towards the end of that year that the zero bound will remain binding throughout 2010, the GDP impact of the government spending stimulus will turn out more similar to the simulations in the left panel.

Recently, other studies have investigated the consequences of fiscal policy when monetary policy is constrained at the zero bound (see Christiano, Eichenbaum, and Rebelo (2009) and Bodenstein, Erceg, and Guerrieri (2009)). Christiano et al. (2009), in particular, have emphasized that under certain conditions fiscal multipliers can get very large, with the GDP impact being three or four times as large as the increase in government spending. The differences between their findings and ours are not due to fundamental differences in the models, but to the nature of the question that is posed. While Cogan et al. (2009) and this paper focus on the expected outcome in scenarios we consider most likely at the current juncture, Christiano et al. (2009) ask what scenarios would generate a very large multiplier. Such cases arise in situations when the zero bound is binding for a much longer time, or in the case of deflation scares that may then averted by fiscal stimulus. Consider a deflation scare that implies an expectation of -4% deflation. If fiscal stimulus is effective in reversing inflation expectations, real interest rates drop dramatically and a large multiplier effect results. For this reason, Coenen et al. (2004) assumed an endogenous response of government spending to deflation below a certain threshold to rule out deflationary spirals. However, such outcomes are contingent on the absence of any other monetary policy action that would avert the deflation and deflation scares such as quantitative easing and large-scale asset purchases as proposed in Orphanides and Wieland (2000) and Coenen and Wieland (2003). Given that the Federal Reserve used asset purchases aggressively to avoid sustained deflation expectations in the United States and euro area inflation expectations largely remained positive, neither the ARRA legislation nor the EERP stimulus should be expected to deliver multiplier effects of the magnitude studied in Christiano et al. (2009).

## 5 Model uncertainty and decision criteria

What should one make of these differential assessments with multiple macroeconomic models? We propose to focus on the cumulative effect of government expenditures on GDP relative to the resources spent by the government. This difference provides a sharp distinction between crowding-in and crowding-out effects and should be of particular interest to policymakers. If increased government spending is likely to stimulate additional private spending, the case for discretionary stimulus is strengthened. But if on top of the recessionary impact on consumption and investment, private spending is pushed further down by crowding-out effects from government spending, such policy action would appear much less attractive. Policymakers may replace it with direct transfers or tax cuts, which would at least avoid reducing private spending, or they may want to forego discretionary stimulus altogether and rely on the automatic fiscal stabilizers and monetary policy for cushioning

the effect of recessions. Even more so as the discretionary stimulus will add further to government debt down the road. We will abstain from an analysis of economic welfare. Although, some of the models considered would allow us to calculate consumer welfare, the utility of representative households may not be considered very practical by policy makers as a guide in a downturn that imposes unemployment or asset losses on some households but not on others.

We calculate the cumulative GDP effect net of government spending for two-year and four-year horizons that would be of particular interest to the elected governments that initiated the euro area fiscal stimulus. These values are reported in **Table 2** for the baseline simulations shown previously in **Figures 1 and 3**. The first column shows the cumulative effect from the first quarter of 2009 to the first quarter of 2011. Over this period, the three New-Keynesian DSGE models and the Taylor (1993) indicate significant private spending displacement. Only the ECB's area-wide model suggests a small net increase. However, over a four-year horizon all five models agree that government spending will crowd-out private spending to a significant extent as shown in the second column.

Table 2: Cumulative GDP net of government spending  
Baseline scenario: no implementation lag & no constant interest rate

	Percentage increase in real GDP		
	EU fiscal package (2011Q1)	EU fiscal package (2013Q4)	US fiscal package (2013Q4)
Smets and Wouters (2003)	-0.15	-0.24	-1.35
Small IMF Model	-0.26	-0.43	-1.79
EU Quest Model	-0.18	-0.14	-1.28
Taylor (1993)	-0.13	-0.21	-0.79
ECB Area Wide Model	0.31	-0.32	-0.18

Notes: Euro area fiscal stimulus package with no monetary accomodation assumed for the results in column 2 and 3. The cumulated euro area stimulus amounts to 0.68 percent of euro area GDP (see table 1) and the cumulated US government purchases to 2.2 percent of US GDP.

Would the results be better if only the euro area governments would have enacted a greater and longer-lasting fiscal stimulus as recommended by the U.S. administration? As a counterfactual we consider the case in which euro area governments implement a package similar in magnitude and length to the ARRA legislation. To this end, we study the impact of the government purchases simulated by Cogan et al. (2009) for the United States in the models of the euro area economy. This package implies significant additional spending for four years. The cumulative impact on GDP net of government spending by the end of the fourth year is shown in the third column of **Table 2**. The four New Keynesian models indicate that a longer-lasting fiscal stimulus will cause greater crowding out of private consumption and investment. Thus, the preference of euro area governments for temporary stimulus is supported by these models. In the ECB's area-wide model the negative overshooting effect

is delayed resulting in a smaller crowding-out effect than under the two-year euro area package.

In the preceding section we investigated several issues that may influence the GDP effect of government spending recession, focusing in particular on implementation lags and zero bound effects. **Table 3** assesses these effects in combination. Implementation lags clearly reinforce the message of the baseline simulations. Crowding out of consumption and investment dominates all cases over the four-year horizon, and for all four New-Keynesian models over the two-year horizon. The cumulative reduction in private-spending in the three DSGE models is noticeably greater than in the baseline scenario in **Table 2**.

Table 3: Cumulative GDP net of government spending

	EU fiscal package: Percentage increase in real GDP	
	cumulated to 2011Q1	cumulated to 2013Q4
Implementation lag		
Smets and Wouters (2003)	-0.25	-0.33
Small IMF Model	-0.32	-0.54
EU Quest Model	-0.30	-0.24
Taylor (1993)	-0.10	-0.21
ECB Area Wide Model	0.20	-0.16
Implementation lag & constant interest in 2009		
Smets and Wouters (2003)	-0.22	-0.30
Small IMF Model	-0.26	-0.48
EU Quest Model	-0.16	-0.07
Taylor (1993)	0.02	-0.09
ECB Area Wide Model	0.22	-0.11
Implementation lag & constant interest 2009-2010		
Smets and Wouters (2003)	-0.11	-0.16
Small IMF Model	0.10	-0.10
EU Quest Model	0.35	0.61
Taylor (1993)	0.51	0.45
ECB Area Wide Model	0.32	0.34
Implementation lag & constant interest in 2009 anticipated 09Q1 & constant interest in 2010 anticipated in 10Q1		
Smets and Wouters (2003)	-0.19	-0.25
Small IMF Model	-0.16	-0.33
EU Quest Model	-0.01	0.16
Taylor (1993)	0.20	0.14
ECB Area Wide Model	0.29	0.29

Notes: The table includes robustness scenarios. We consider monetary accommodation of 1 and 2 years and an implementation lag of 2 quarters. The cumulated euro area stimulus amounts to 0.68 percent of euro area GDP (see table 1).

If the notional interest target of the central bank moves below zero during the recession and stays there long enough for the zero bound to bind throughout all of 2009, interest rates would not rise as

usually implied by the policy rule in response to fiscal stimulus throughout that year. This effect is taken into account in our simulations by the anticipation of constant interest rates throughout 2009. As a result the initial GDP effect of government spending is somewhat greater because the usual increase in real interest rates is delayed. The cumulative sums net of government spending in the five models are reported in the second set of rows in **Table 2**. Again, crowding-out of private spending occurs in the three current-generation New-Keynesian models over two- and four-year horizons, and in all five models over the four-year horizon.

Crowding-in of private consumption and investment only occurs to a noticeable extent if interest rates are anticipated to remain constant till the end of 2010 as early as the first quarter of 2009. Of course, in this simulation inflation also increases more. In the New-Keynesian models the date and extent of the anticipation of households and firms play an important role. We illustrate this by analyzing the following scenario. Initially market participants expect monetary accommodation in 2009 but a return to the policy rule in 2010. New information on the central bank's intentions then leads them to update their expectations for another year of monetary accommodation at the beginning of 2010. The resulting outcomes for the GDP impact of fiscal stimulus in the DSGE models are closer to the case with 1-year of constant interest rates with crowding out of private consumption and investment.<sup>16</sup>

## 6 Other approaches in the literature

In our analysis of the effects of government spending, we have focused on estimates obtained with structural models of the euro area. Structural models are needed to dissect the effects of anticipations by market participants under alternative assumptions regarding the timing of fiscal stimulus and the interaction with monetary policy. We found that such anticipation effects have important implications for the degree of crowding-out of private spending by increased government purchases.

However, there also exists a large empirical literature that utilizes reduced-form methods in order to identify the likely effects of government spending shocks. Many of these studies focus on U.S. data, but others also cover a wide range of OECD economies. As emphasized by Ramey (2009) the U.S. studies remain divided on central questions such as whether the GDP effect is greater than unity and whether private spending rises or falls in response to additional government purchases. VAR techniques in which identification is achieved by assuming that government spending is pre-determined within the quarter typically find a larger effect of government spending on GDP and crowding-in of consumption (e.g. Blanchard and Perotti (2002), Fatas and Mihov (2001), Beetsma,

<sup>16</sup>As to actual developments in the euro area, the ECB stopped lowering its overnight lending rate at 1% and its deposit rate at 0.25% in May 2009 calling this an appropriate level. As of September 2009 it already started to lay out its strategy for exit from this monetary policy stance. The advent of European fiscal crisis in spring 2010 instead provided a new motivation for maintaining the low level of nominal policy rates.

Giuliodori, and Klaassen (2006) or Gali et al. (2007)) while studies using the Ramey-Shapiro "war dates" (e.g. Ramey and Shapiro (1998), Burnside, Eichenbaum, and Fisher (2004), Ramey (2009)) indicate a smaller GDP effect and crowding-out of consumption. Indeed, these studies and other more recent ones reveal a wide range of estimates of the GDP impact of government spending due to difficulties in identifying the presumed government spending shocks. Using VAR techniques, Blanchard and Perotti (2002) find a government spending multiplier close to one, Fatas and Mihov (2001) estimate it to be greater than one, Beetsma et al. (2006) put it at 1.5 by the second year for a range of European economies, while Gali et al. (2007) obtain a high-end estimate of 1.7 after two years. These studies suggest that private consumption increases following a government spending shock. Perotti (2005) looks at data from five OECD countries including Germany. He finds that the effects of government spending on GDP tend to be small and below unity except for the U.S. data. Furthermore, the GDP effect of government spending appears to have become weaker since the 1980s. Using a different identification approach based on sign restrictions, Mountford and Uhlig (2009) estimate a multiplier well below one for a deficit financed government spending shock with substantial crowding-out of investment.

Clearly, identification is a problem. Ramey (2009) shows that increases in U.S. military spending and non-defense spending are anticipated several quarters before they occur. Consequently, it is important to capture the timing of the news about future increases government spending correctly. Her multiplier estimates based on an war dates and defense news lie between 0.6 and 0.8 when World War II is excluded, and near unity with World War II included. Similar empirical findings are reported by Barro and Redlick (2009). They identify a defense spending multiplier of 0.6 to 0.7 including the World War II period and find a significant negative effect of defense-spending shocks on private investment. A recent paper by Afonso, Grüner, and Kolerus (2010) analyses empirically if the impact of government spending on GDP differs in crisis and non crisis times. They employ data of OECD and non-OECD countries for the period 1981-2007 and use panel regression techniques. To overcome endogeneity problems they use the distance to next and past elections and lagged budget balance-to-GDP ratios as instruments for government spending. They cannot reject the hypothesis that crisis spending and regular spending have the same impact on GDP and find an average fiscal multiplier between 0.6 and 0.8 for the full sample.

How does this work relate to our analysis of the U.S. and euro area stimulus packages with structural models? The timing and nature of the anticipation of fiscal spending packages due to the ARRA and EERP is known and need not be identified from macroeconomic time series. Of course, in estimating the structural models one also obtains empirical monetary and fiscal policy reaction functions. In Cogan et al. (2010) we use them to conduct simulations that are similar to the experiments in VAR studies, namely a one-time surprise increase in government spending that dies out slowly according

to an anticipated autoregressive process. They show that the effect of a typical government spending shock in the DSGE models with and without rule-of-thumb consumers estimated for the United States is about 0.8 averaged over the first year, and thus similar to several of the above-mentioned reduced-form studies. The euro area DSGE models considered in this paper fit well in this range.

Following the 2009 working papers by Romer and Bernstein (2009), Cogan et al. (2009) and Cwik and Wieland (2009) an increasing number of studies have used other structural macroeconomic models to assess the impact of different fiscal policy tools. An interesting extension of the EU-Quest model by Roeger and in't Veld (2009) includes a third type of households that are credit-constrained. Their benchmark calibration apparently has 40% liquidity-constrained households and another 20% credit constrained households, which would be too high relative to the survey evidence available regarding the share of such households during the financial crisis. The IMF's new preferred model for fiscal policy analysis, the so-called GIMF model, has been used by Freedman, Kumhof, Laxton, Muir, and Mursula (2010) to analyze the consequences of different fiscal measures. An innovative element of this model is that it features overlapping generations of households with finite horizons. As shown by Taylor (2010b) the effects of longer-lasting or permanent fiscal stimuli in the GIMF are very close to the effects reported by Cogan et al. (2010) for New-Keynesian DSGE models. A short-term government spending shock in GIMF has a multiplier of unity under normal circumstances which is larger than in the DSGE models considered in Cogan et al. (2010) and this paper. Unfortunately, the GIMF model is calibrated and not estimated with state-of-the-art methods to fit US or euro area data. It would be very useful to see how it fares in estimation relative to the estimated models we have used.

Recently, a very commendable model comparison study was executed by 17 researchers from the IMF, OECD, ECB, Federal Reserve and European Commission in Coenen, Erceg, Freedman, Furceri, Kumhof, Lalonde, Laxton, Lindé, Mourougane, Muir, Mursula, de Resende, Roberts, Roeger, Snud-den, Trabandt, and in't Veld (2010). It covers seven structural models used at policy institutions including GIMF, the modified version of EU-Quest with additional constrained households, the Fed's SIGMA and FRB-US models, the OECD Fiscal Model, the Bank of Canada-GEM model and the ECB's New Area-Wide Model. The study refers to Cogan et al. (2009) but ignores the model comparison for the euro area by Cwik and Wieland (2009) from July 2009. They mostly find somewhat higher short-run government purchases multipliers than Cogan et al. (2009) and attribute this difference to the assumption of rule-of-thumb households. Indeed, three of these models includes shares of 40 or 50% which is higher than the 28% share estimated by Cogan et al. (2009) and the shares of 13 to 25 % reported by the survey studies cited earlier. Coenen et al. (2010) tend to put greater emphasis on the simulations with anticipation of two full years of monetary accommodation right at the start of 2009 when fiscal stimulus was announced. However, they ignore the possibility of even moderate

implementation lags.

Further comparison of our findings with those by Coenen et al. (2010) would be very useful. Unfortunately, Coenen et al. (2010) employ a traditional model comparison as in Taylor (1999) whereby separate teams of researchers conduct a specific set of experiments, each team in their own model and report outcomes. It would be very useful if the policy institutions that are represented by these researcher teams would choose to create a platform for model comparison as in Wieland et al. (2009) or add their models to this new model database. Such a platform would render their model simulations also directly replicable and transparent to researchers outside these teams and institutions. Replicability is a basic scientific standard that ensures that correct comparisons can be made and policy recommendations can be properly scrutinized. Several of these institutions have already made earlier models publicly available for such purposes and the publication of the Coenen et al. (2010) would seem to provide a perfect occasion to proceed accordingly.

## 7 Government spending spillover effects in the euro area

Advocates of fiscal stimulus in the euro area were particularly concerned with spillover effects and the potential for free-riding. The rationale was that unilateral stimulus in one country, for example in Spain, would partly be diverted to a greater demand for import goods. As a result, other euro area trading partners, say Germany, France or Italy, would benefit from Spanish fiscal stimulus. They would even have an incentive to go slow on domestic stimulus while encouraging other countries, a behavior referred to as "free-riding". This criticism was directed in particular at the German government that was perceived to have most room for additional fiscal spending thanks to past budget consolidation.<sup>17</sup> As indicated by our review of announced fiscal packages in the euro area, the German government eventually announced by far the largest fiscal stimulus measures accounting for 51 % of the total euro area stimulus. Thus, the question now is whether the effect of German government spending increases will pull along other euro area countries. Analyzing this question requires an estimated macroeconomic multi-country model that accounts for a sufficient number of euro area member economies separately. Unfortunately, such models are still relatively rare. One model at our disposal is the Taylor (1993) model of the G7 economies. We use it to quantify the effect of the spending measures announced by the German government on Germany, France and Italy.

**Table 4** reports the effects on German, French and Italian GDP from the first quarter of 2009 to the fourth quarter of 2012. The first three rows indicate the outcome when these countries form a monetary union, in other words, when the exchange rates are fixed and monetary policy aims at stabilizing union-wide targets. Interestingly, the spill-over effects are rather small. In Italy they even turn negative by the end of 2009. This finding is obtained even though the estimated export demand

<sup>17</sup>An example, is the contribution of Paul Krugman cited in the first footnote in the introduction.

equations for Italy and France indicate an economically significant direct foreign demand effect with Germany as an important trading partner. This direct demand effect is overwhelmed by the indirect effect of a real appreciation of the Euro. The fiscal expansion in Germany puts upward pressure on the euro relative to the currencies of countries outside the monetary union (United States, Canada, United Kingdom and Japan). As a result, France and Italy loose competitiveness and exports to countries outside the euro area decline.

Table 4: Impact of German government expenditures

	Percentage increase in real GDP				
	2009Q1	2009Q4	2010Q4	2011Q4	2012Q4
<i>Monetary union</i>					
France	0.037	0.035	0.010	-0.009	0.002
Germany	0.700	0.645	0.368	-0.078	-0.136
Italy	0.014	-0.009	-0.046	-0.052	-0.018
<i>Flexible exchange rates</i>					
France	0.053	0.060	0.019	-0.018	-0.012
Germany	0.636	0.493	0.224	-0.112	-0.063
Italy	0.043	0.052	0.023	-0.014	-0.015

Notes: The impact of the German fiscal stimulus package is simulated with the Taylor-Model. Euro area inflation and output gap are defined as a weighted average of German, French and Italian values. In the case of the monetary union simulation the euro area nominal interest rate reacts to euro area inflation and output gap. We assume no change in the fiscal policy of France and Italy.

Our findings differ from estimates of intra-European spillover effects obtained by Beetsma et al. (2006). They estimate reduced-form trade equations and link them to VAR-based estimates of domestic demand effects of government spending. A government spending increase of 1% of GDP in Germany is then estimated to raise output in other euro area countries by 0.05 to 0.45 percent. However, Wieland (2006) points out that the data sample used by Beetsma et al. (2006), namely 1965 to 2004, covers monetary and exchange rate regime changes. At the beginning, exchange rates were flexible, during the EMS period they were temporarily fixed but regularly adjusted in exchange rate re-alignments until they became permanently fixed at the start of the euro area. Monetary policy changed from independent national monetary policies, then some period of Bundesbank leadership in the EMS to a single euro area policy. The estimates obtained by Beetsma et al. (2006) may be unduly biased by ignoring these regime changes. In particular, positive spillovers in periods of fairly flexible exchange rates contrast with small or even negative spillovers in periods of fixed exchange rates as shown in Wieland (1996).

To further explore the role of the exchange rate in fiscal stimulus we conduct a counterfactual simulation with flexible exchange rates between France, Germany and Italy and independent mon-

etary policies. In this case, the effect of fiscal stimulus in Germany is reduced, because it is faced with a larger appreciation of its currency vis-a-vis others. The spill-over effects to France and Italy, however, would be positive. As emphasized by Wieland (2006) it is important to account for this regime change in assessing the extent of likely spill-overs between euro area member economies. The exchange rate appreciates on impact of the stimulus, because interest rates are expected to rise and capital flows into the country. While empirical VAR studies that use data from before and after monetary union will confound the differential spill-over effects from these two periods, they may be distinguished by using a structural model. It would be of interest to estimate a New-Keynesian DSGE model of the G-7 economies with more recent data and conduct a robustness analysis.

## 8 Government investment and transfers

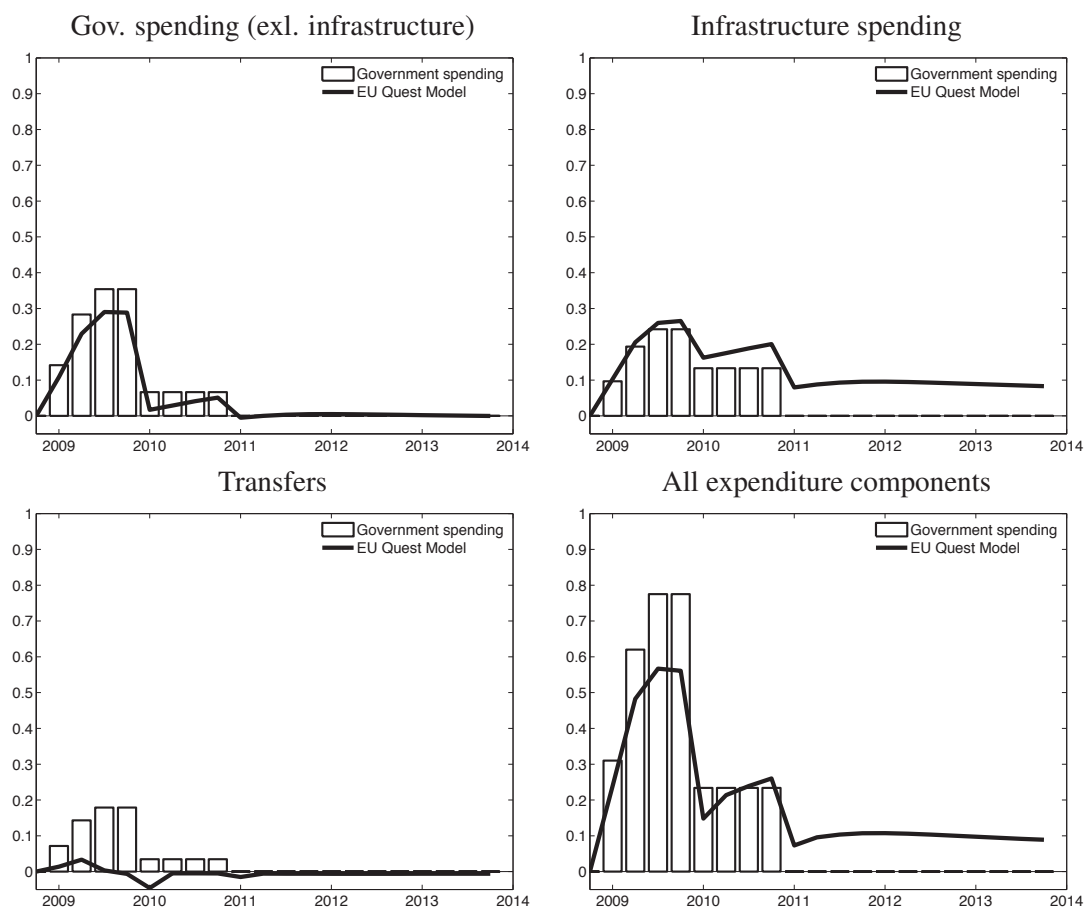

Advocates of fiscal stimulus also often praise the additional benefits that can be obtained from government spending on infrastructure and other private sector productivity enhancing investments to further the case for fiscal stimulus. Indeed, government expenditure on such infrastructure is important but it may not be advisable to tie such construction to stimulus packages that are aimed to be executed rapidly. Implementation lags are sure to be greatest with regard to major new infrastructure construction. Leeper, Walker, and Yang (2009), for example, argue that due to implementation lags expansionary government investment can cause a short-run contraction of output. And if pressure is applied to accelerate spending of allocated funds, inefficient use and wastage due to inadequate planning and insufficient competition is likely to be the result.

We have reviewed the stability programmes of national governments from 2008/2009 to separate spending on infrastructure from other spending measures. We have focused on infrastructure rather than simply checking whether the label "investment" is assigned to a particular measure. The reason is that there is a natural tendency to qualify government initiatives as a form of investment rather than consumption for public relations purposes. In some cases, in which measures were targeted only partly at building new infrastructure without specification of the share, we assumed a share of 50 %. Further details for each country are reported in the appendix.

To investigate the potential GDP impact of government investment, we turn to the EU-Quest model. This model assumes that government investment helps raise overall production in the longer run. The extent of this effect is shown in the top right panel of **Figure 7**. The bars refer to the amount of infrastructure spending as a percent of GDP. The solid line depicts the impact of this spending on GDP in the EU-Quest model. In this simulation, we abstract from implementation lags or monetary accommodation. For comparison, the effect of the non-infrastructure component of spending is simulated in the top left panel. Throughout 2009, government investment has similar effect as government consumption in the EU-Quest model. In the second and subsequent years the

productive effect kicks and output rises above level of the government consumption simulation. It has to be acknowledged, however, that the productive effect of the public capital on overall output in the economy is essentially assumed. Further research on the appropriate role of government investments in private sector production functions would be useful.

Figure 7: GDP impact of expenditure-side stimulus components in EU-QUEST Model

Notes: Baseline scenario without delay and without monetary accommodation.

So far, we have not discussed the likely impact of the transfer and tax cut components of fiscal stimulus. The reason is that most of the models we have considered have little to say on the impact of these measures. The SW and Small IMF model assume non-distortionary lump-sum taxation and transfers and only contain optimizing households. As a consequence of these assumptions, temporary tax cuts and transfer increases will not affect household life-time income. Also, the Taylor model does not account for taxes and transfers explicitly. The EU-Quest model, however, has a share of 35 % of rule-of-thumb households and includes estimated reaction functions for government spending, tax rates and transfers. Thus, we have simulated the transfers we identified in the euro area fiscal packages in the EU-Quest model. The lower left panel of **Figure 7** depicts the magnitude of these

transfers (bars) and the resulting impact on GDP in that model (solid line). The effect on GDP remains very small. The lower-right panel reports the total euro area measures on the expenditure-side of the government budget and their impact on GDP in the EU-Quest model.

## 9 What has happened so far? A 2010 perspective

Having focused so far, on investigating the likely effect of announced government spending in the context of the EERP and national stimulus packages, it is worth taking stock of what has happened since these announcements. One question of great interest would be whether these plans were carried and to what extent they were implemented with some delay. For the United States, the Bureau of Economic Analysis has published information on the stimulus money spent and its impact on the government sector in the quarterly national accounts. A comparison between the planned increases in government purchases underlying the simulations conducted by Cogan et al. (2010) and the actual spending up to the second quarter of 2010 indicates that spending built up over time but stayed a bit below the projected amounts. It would be very useful if the European Commission and national euro area governments would similarly publish information on the actual spending pattern regarding the announced measures. This information is crucial for appropriate ex-post evaluations of their effectiveness. We have contacted experts at the European Commission and at the German finance ministry but so far we have not been able to obtain such information nor to find out whether authorities are conducting or planning to conduct such an ex-post assessment.

A narrative that we have heard repeatedly being told in policy circles or the media is that fiscal stimulus played a crucial role in the recovery that started in the second quarter of 2009, and that its removal at the end of 2010 may cause economies to fall back into recession. In the absence of any information on actual stimulus spending carried out, we take a look at the available aggregate national accounts data on government spending. The top left panel of **Figure 8** reports the real GDP growth contribution of government spending (red line) in the euro area from the first quarter of 2007 up to and including the second quarter of 2010. It is rather flat and declines slightly towards the second half of 2009. By contrast, real GDP growth (blue line) collapsed from the first quarter of 2008 to the second quarter of 2009 and then started to recover in the second half of 2009 and accelerated at the beginning of 2010. It would seem to be difficult to make a case for a crucial role of government spending in stimulating growth based on the inspection of this chart.

The lower-left panel plots the real GDP growth contribution coming from private consumption. Consumption declines somewhat during the recession and picks up again in the second half of 2009. Consumption growth variation, however, is rather small relative to variation in GDP growth. This observation, at least, is not inconsistent with the consumption-smoothing implication of the permanent-income hypothesis. As shown in the top right panel, the real GDP growth contribution of fixed invest-

ment explains much of the variation in GDP growth, together with significant contributions coming from net exports and inventory investment (lower right panel). This observation suggests that factors such as real interest rates, risk premia and credit availability that influence investment and net exports receive a crucial role in any explanation of the recession and recovery. Regarding policy actions, possible candidates that may have influenced the cost and availability of credit include central bank interest rate cuts, credit and quantitative easing measures, as well as guarantees and capital injections for financial institutions.

Figure 8: GDP growth contributions throughout the 2008-2010 recession and recovery

Notes: Real GDP growth and growth contributions of GDP components. Source: ECB. Vintage: September 2010.

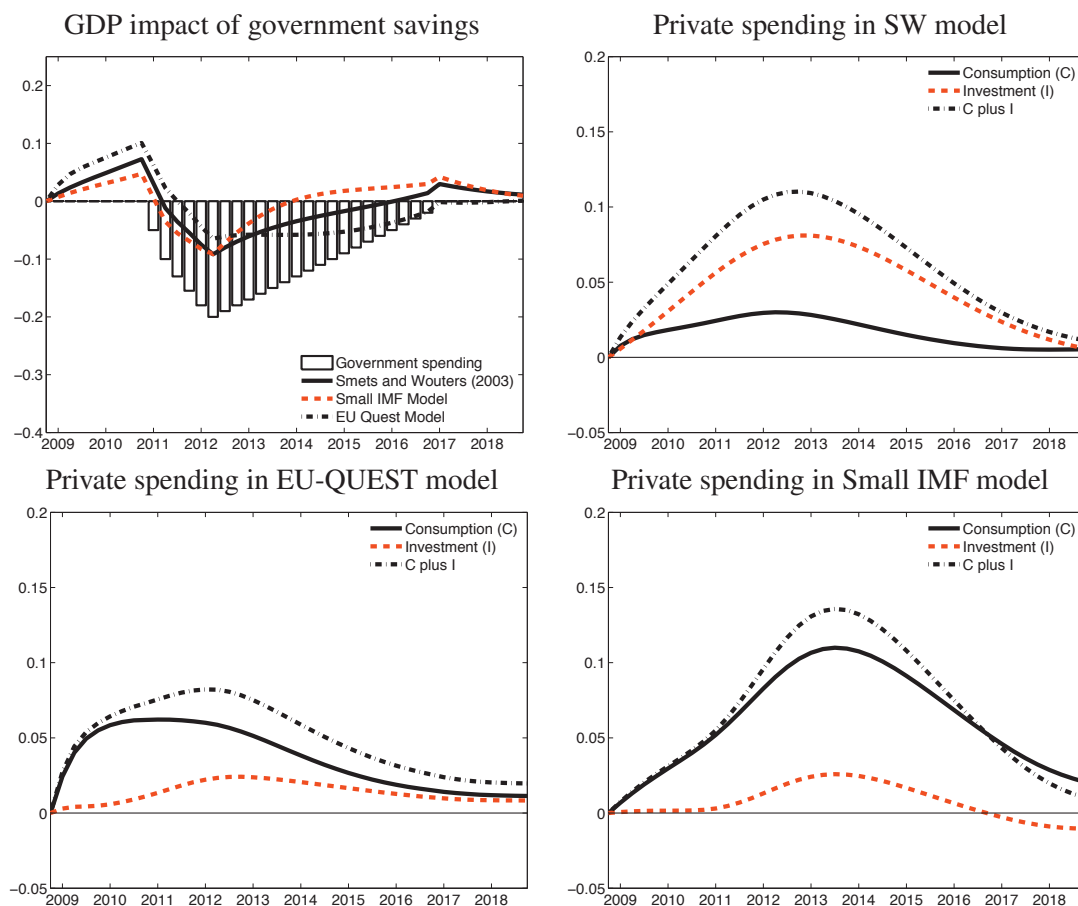

## 10 Consolidation-cum-stimulus: Estimated effects of government savings packages

Looking forward, the observed rapid increase in government indebtedness raises the question of when and how to start consolidating government finances. Many supporters of fiscal stimulus in the recession tend to worry about negative fall-out for economic activity coming from the expectation of fiscal consolidation. We aim to address this concern by simulating the consequences of government spending cuts in the models under consideration. Not surprisingly, the ECB's Area-Wide model that assumes largely backward-looking behavior exhibits symmetric behavior under government spending and government savings packages and supports concerns about the negative impact of impending

fiscal consolidation.

Answers to these questions based on the current generation of New-Keynesian DSGE models may be quite different. Of course, if we simply consider the mirror image of the baseline stimulus package in **Figure 1** in the SW, Small IMF and EU Quest models in form of spending cuts, the resulting behavior of GDP will be symmetric to the outcome shown there. But these models point to an important role of private sector anticipations of government policies. Thus, we consider a counterfactual scenario that goes as follows. Assume that instead of announcing a government spending increase for 2009 and 2010 at the start of 2009, euro area governments would have instead announced a government savings package consisting of spending cuts that would be slowly phased in from the first quarter of 2011 onwards and spread over six years. The reduction in government spending would be equivalent (in un-discounted terms) to the increase in government spending implied by the fiscal stimulus packages in **Table 1**.

Figure 9: A government savings stimulus and private sector spending

Notes: Savings plan in the size of the euro area fiscal stimulus package from 2011Q1 on. No monetary accomodation.

The path of announced spending cuts is displayed by the bars in the top left panel of **Figure 9**.

Implementation lags are no issue, because government authorities have two years lead-time for planning and executing this reduction in government purchases. Given the consolidation plan is credible, households and firms will anticipate it as of the first quarter of 2009. It will imply a reduction in current or future taxation that increases household life-time income. As a result, households will start to consume more. Similarly, the positive wealth effect impacts investment. Expected real interest rates decline, the price of capital rises and private investment goes up. As a consequence GDP increases throughout 2008 and 2009 in all three New-Keynesian DSGE models as indicated by the solid, dashed and dotted lines in the top-left panel of **Figure 9**. This crowding-in effect is largest in the EU-Quest model due to the presence of 35% of rule-of-thumb consumers. The short-run multiplier in 2009 and 2010 is infinite because no government spending occurs. From 2011 onwards GDP declines as government spending cuts kick in. The trough is reached in 2012. It is of similar absolute magnitude as the peak effect in 2010. As can be seen in the top right and bottom panels of **Figure 9**, private consumption and investment spending remains above baseline throughout the full 6-year period of fiscal consolidation.

In practice, taxes are mostly distortionary and not lump-sum. Thus, spending cuts would allow a reduction in distortionary taxation with positive effect on longer-run growth. If consolidation and debt reduction are a priority, then some of the savings could be applied to debt reduction rather than tax cuts and short-run stimulus.

The idea for the proposal of government savings packages is related to the analysis of government spending shocks by Corsetti, Meier, and Mueller (2009) and Corsetti, Meier, and Mueller (2010). Based on VAR studies they argue that positive government spending shocks are followed by a decline in government spending that turns to spending cuts about 9 quarters after the initial shock. Then they implement this government spending process in a calibrated New-Keynesian DSGE model and show that the anticipation of future spending cuts induces a greater initial multiplier effect with some crowding in of consumption. Wieland (2010) finds that the ratio of anticipated spending cuts to spending increases in absolute value is 1.1. Thus, future spending cuts are greater than initial increases. Neither the ARRA nor the EERP stimulus packages included announcements of such substantial future spending cuts. Furthermore, there is no indication that market participants in the United States or Europe formed an expectation of spending cuts of equal or greater size than these stimulus packages in the first quarter of 2009. Wieland (2010) therefore concludes that the empirical case for expecting such cuts upon announcement of the stimulus packages is rather weak.

New-Keynesian DSGE models, however, generate a strong normative prescription. Properly designed government savings packages announced with sufficient lead time can provide significant short-run stimulus. If such a plan had been announced in the beginning of 2009 it could have boosted private spending in 2009 and 2010. This boost would have been re-inforced further in case of mon-

etary accommodation due to zero-bound effects. **Figure 10** illustrates the additional boost to private spending and GDP if nominal interest rates are anticipated to remain constant in 2009 and 2010.

Figure 10: Government savings stimulus when nominal interest remains constant

## 11 Conclusions

In this paper we have constructed an estimate of the additional government expenditures in the euro area in conjunction with the measures announced in national fiscal stimulus packages for 2009 and 2010. According to our calculations the euro area stimulus is primarily driven by measures taken by the German government and to a smaller part by the Spanish and French governments. We have then used a comparative, model-based approach to assess the likely impact of these measures on euro area GDP. Proponents of discretionary fiscal stimulus emphasize the Keynesian multiplier effect that implies that additional government spending would induce an increase in private spending and therefore a greater than one-for-one effect on aggregate GDP. We investigate this proposition by using empirical macroeconomic models with Keynesian features such as price and wage rigidities. Four of the models we use have been developed and estimated at central banks and international institutions. Three of these models are New-Keynesian DSGE models that represent the current state of the art of policy analysis.

In the baseline scenario, New-Keynesian models do not support a text-book Keynesian multiplier effect. The European government spending plans would result in a reduction in private sector spending for consumption and investment purposes. The reason is the forward-looking behavior of households and firms. They anticipate higher tax burdens and higher interest rates in the future and therefore reduce consumption and investment. Only the ECB's area-wide model, which largely ignores forward-looking behavior, is found to generate government spending multipliers that are significantly above one. Although such models are useful for short-term forecasting in the absence of

major policy changes they are not well-suited for analyzing the effect of such changes. The New-Keynesian models instead account for the likely response of forward-looking optimizing households and firms.

We then discuss a number of factors that may have played a role in the recession of 2008 and 2009. Time lags arise because of the steps needed to move from a timely announcement to actual implementation of government spending plans. Such implementation lags lead to more crowding out and may even cause an initial contraction. In a deep recession, the zero-bound on nominal interest rates may cause the central bank to abstain to raise interest rates in response to fiscal stimulus as in normal times, because its notional interest target is below zero. Such implicit monetary accommodation increases the GDP impact of government spending. Crowding-in, however, requires an immediate anticipation of at least two years at the zero bound.

We have also analyzed the possibility of spillover effects within the euro area using the Taylor (1993) model. This model, which assumes forward-looking, rational expectations and price and wage rigidities, accounts for the French, German and Italian economies separately. The spillover effects of the German stimulus measures with regard to France are very small. They even turn slightly negative in the case of Italy at the end of 2009. Direct demand effects are overwhelmed by the indirect effect of an euro appreciation. For further research on euro area spillovers it would be of interest to estimate a multi-country New-Keynesian DSGE model with more recent data and conduct a robustness analysis.

In this paper, we have investigated the possibility of Keynesian multiplier effects using empirical macroeconomic models with Keynesian features. In contrast with real business cycle models, the estimated New-Keynesian models assume "sticky prices" by introducing staggered price and wage setting. But as Chari, Kehoe, and McGrattan (2009) have emphasized the models go further in the Keynesian direction by assuming "the backward indexation of prices" in "a mechanical way" which amplifies Keynesian aggregate demand effects of policy. Addressing this criticism by eliminating these features from the New Keynesian models would tend to further strengthen the case against discretionary fiscal stimulus. For example, Uhlig (2009) considers a neoclassical growth model with endogenous labor and various fiscal instruments and concludes that massive expansions in government spending such as the ARRA package in the United States come at substantial costs in terms of total output over the longer run.

Finally, we have turned to the question of fiscal consolidation. We illustrate that New-Keynesian DSGE models provide a strong-case for government savings packages. Announced with sufficient lead time, anticipated future spending cuts induce a significant short-run stimulus and sustained crowding-in of private spending.

## A Country details on the fiscal packages in the euro area (in bln Euro)

### A.1 Austria

Category	Measure	2009	2010
Tax cuts	Early implementation of income tax reform	2.30	2.30
	Degressive depreciation deduction	0.23	0.34
	Reduced VAT rate on medication	0.28	0.28
	Tax exemptions	0.16	0.16
	Burden reduction for families with children	0.51	0.51
		<b>3.48</b>	<b>3.59</b>
Government spending (excl. infrastructure)	Mandatory kindergarten year for all	0.07	0.07
	Regional employment initiatives	0.08	0.08
	Spending package, September 2008	0.40	0.00
	Investment in public facilities	0.36	0.52
	Energy saving cheques	0.10	0.00
	Additional research expenditure	0.05	0.05
	"Mittelstandsfonds"- venture capital fund for SMEs	0.04	0.04
		<b>1.10</b>	<b>0.76</b>
Government spending (infrastructure)	Advancing of railroad investments	0.24	0.24
	Investments into broad-band internet infrastructure	0.01	0.00
		<b>0.25</b>	<b>0.24</b>
Transfers	Subsidies to house saving scheme	0.02	0.02
		<b>0.02</b>	<b>0.02</b>

### A.3 Germany

Category	Measure	2009	2010
Tax cuts	Degressive depreciation deduction	1.94	4.33
	Higher tax-free allowances for companies	0.24	0.37
	Suspension of car tax on on new vehicles	0.44	0.13
	Tax deductibility of professional commute	4.00	4.00
	Package for tax burden reduction, stabilisation of		
	Social security contributions and investment in families	4.22	12.04
	Income tax cut	2.90	6.04
	Reduction in health insurance contributions	3.00	6.50
	State payment of 50 percent social insurance for short-time workers	1.15	1.15
	Reform of car tax	0.09	0.17
		<b>17.98</b>	<b>34.73</b>
Government spending (excl. infrastructure)	Premium for new car purchases	5.00	0.00
	Retraining and stronger job service	1.59	1.59
	Improvement of regional economic structure	0.30	0.00
	Innovation support programme	0.45	0.45
		<b>7.34</b>	<b>2.04</b>
Government spending (infrastructure)	Investments into transport infrastructure	1.00	1.00
	Infrastructure investment programme	8.65	8.68
		<b>9.65</b>	<b>9.68</b>
Transfers	Increased child benefits	4.42	2.84
	Increased housing benefits	0.06	0.06
		<b>4.48</b>	<b>2.90</b>
